Abstract

Dynamical focusing of ensembles of neutral particles in energy and configuration space has been demonstrated recently [C. Petri et al. 2010, Phys. Rev. E (R) **82**, 035204] using time-dependent elliptical billiards. The interplay of nonlinearity, dissipation and driving yields the occurrence of attractors in the phase space of the billiard. Here we show that dissipative oval billiards with slowly oscillating elliptical scatterers in the interior allow for a dynamical focusing on simple periodic trajectories with close to perfect efficiency. This setup should be more amenable to corresponding experiments which are briefly discussed.

Introduction Exhibiting typical phenomena occurring in nonlinear systems which are too complex to analyze them directly, billiards have become popular model systems in many areas of physics: the main concepts of quantum chaos could be developed in the context of billiards [1] (and refs. therein), they stimulated the foundations of modern semiclassics [1] and could be related to the Riemann hypothesis [2]. Even a justification of a probabilistic approach to statistical mechanics can be based on billiards [3, 4]. Recently, they could be related to the physics of graphene [5] and have been exploited in order to improve the efficiency of thermoelectric materials [6]. Meanwhile, they are experimentally accessible in a variety of setups such as microwave resonators [1, 7, 8], atom-optical- [9–11], and semiconductor heterostructure based devices [12] as well as quantum dots [13].

In recent years particularly time-dependent billiards attracted much attention. A related key topic is the long-standing quest of the general requirements of the occurrence of Fermi-acceleration [14–16] (and refs. therein), i.e. under which conditions does a system ‘heat up’ unboundedly due to a driving force? The difficulty of a general answer becomes already clear by the exemplary findings, that correlations can either cause the suppression of Fermi-acceleration, as in the one-dimensional Fermi-Ulam model [15, 17, 18] or can even yield exponential acceleration [19–22].

Due to their conceptual simplicity and the complexity of their phenomenology, time-dependent billiards are perfectly suited to employ ideas which are based on characteristic phenomena of complex systems: In [23] the fact that the set of attractors in the phase space of a dissipative nonlinear systems determines its possible asymptotic behavior was employed to an elliptical billiard with a time-dependent boundary in order to achieve a filter for neutral particles, working simultaneously in momentum and configuration space. Cutting a small hole into the boundary a synchronized particle beam is obtained. Such a dynamical particle filter, based on general concepts of nonlinear dynamics provides a simple, versatile and efficient alternative to the extensively used standard filtering-devices such as lenses, nozzles, mirrors or collimators. However, the corresponding results were achieved using a dissipative elliptical billiard with oscillating hard boundaries which are experimentally challenging to realize and turn out to lead to relatively high loss rates in terms of particles stopping inside the billiard.

Static boundaries are comparatively simple to realize and design and lead in combination with a time-dependent scatterer in the interior of the billiard to an alternative dynamical

system. This raises the question, whether particle focusing as demonstrated in [23] can be obtained also in such a setup. A further limitation of [23] concerns the relatively high particle losses due to rotators in the phase space of elliptical billiards [23].

The main goal of this work is to provide and analyze a model which combines experimental simpleness with high-efficiency asymptotic focusing and synchronization of random ensembles of neutral particles on a single periodic trajectory. A billiard with oval boundaries and oscillating elliptical scatterer in the interior is shown to provide the appropriate setup and demonstrated to yield the desired focusing effects for sufficiently slow driving and an elongated shape of the inset.

Motivation of the Model It is first discussed why for the class of billiards with a static boundary and a time-dependent scatterer in the interior, an oval for the former and an ellipse for the latter appears to be the simplest promising setup in order to achieve a highly efficient particle focusing. Then, a corresponding model is proposed. The obvious starting point would be to replace the breathing elliptical boundaries in [23] by static ones and to place a circular, oscillating scatterer in the interior of the billiard. However, due to the presence of rotators in the elliptical billiard [24] relatively high particle losses would be the consequence which can be only avoided by introducing local defects at the boundary [23]. Thus, the natural extension is to consider oval boundaries which in the following turn out to be perfectly tunable to avoid particle losses. Concerning the geometry of the inset, the natural starting point of a circular inset turns out to result either in attractors of chaotic type, i.e. in a non-synchronized, non-periodic asymptotic dynamics or in very low focusing efficiencies. These considerations therefore result in the following model: Consider the dynamics of non-interacting point particles of mass m in a two-dimensional static oval billiard with an oscillating hard scatterer of elliptical shape in the interior (Fig. 1) in the presence of a velocity-proportional friction force $F_R = k \cdot \mathbf{v}$. The static oval boundary is defined as a plain, closed curve $\mathbf{x}_B(\phi)$ parametrized by $0 \leq \phi < 2\pi$ [25]:

$$\begin{aligned} x_B(\phi) &= [(\delta/2 + 1) \sin \phi + (\delta/6) \sin(3\phi)] \\ y_B(\phi) &= [(\delta/2 - 1) \cos \phi - (\delta/6) \cos(3\phi)] \end{aligned} \tag{1}$$

Therein $0 \leq \delta < 1$ is a measure for the deviation of the oval from the circle (which is reobtained for $\delta = 0$) and for the maximal curvature, occurring at $\phi = 0, \pi$. The respective boundary of the oscillating inset can be defined directly by the following coordinate

FIG. 1. Sketch of the oval billiard with the oscillating inset in its interior at two different collision-times (full and short dashed purple line), a typical trajectory (red, long dashed) and the angles α_n, β_n for an exemplary collision with the static boundary.

representation

$$\frac{[x_I - f_x(t)]^2}{A^2} + \frac{[y_I - f_y(t)]^2}{B^2} = 1$$

$$f_x(t) = a \cos(\omega_x t); \quad f_y(t) = b \cos(\omega_y t), \quad (2)$$

where A, B are the semi-major and semi-minor axes of the ellipse and ω_x, ω_y, a, b denote the frequencies and amplitudes of the oscillation in x, y -direction, respectively.

The corresponding free-space dynamics of a particle with coordinates $\mathbf{x} \equiv (x, y)$, initial position $\mathbf{x}_0$ and velocity $\mathbf{v}_0$ is described by the Newtonian equation of motion $m\ddot{\mathbf{x}} + k\dot{\mathbf{x}} = 0$, with the solution

$$\mathbf{x}(t) = \mathbf{x}_0 + \frac{m\mathbf{v}_0}{k} (1 - e^{-(k/m)t}) \quad (3)$$

Thus, particles inside the billiard move on straight lines between successive collisions with boundary/inset and their dynamics can be captured by a mapping from one collision to the next one. Collisions can of course happen in any order with the boundary and inset and not only in an alternating way. Particles which do not hit the driven inset for a sufficiently long time eventually stop and are considered as lost.

In order to minimize losses, the occurrence of rotors in the phase space, corresponding to

particles traveling around the inset without hitting it, must be suppressed. Accordingly, in the following a large deviation of the oval from the circle ($\delta = 0.99$) and mainly elongated insets are chosen (cf. 1).

Mapping: A mapping which describes the dynamics of particles in the billiard from collision to collision is formulated in the following. Let n count the total number of collisions of the particle with the boundary/inset and $t_n, \mathbf{x}_n, \mathbf{v}_n$ denote time, position and velocity at the instance after the corresponding collision. Then, the dynamics of the system can be described by a five-dimensional, non-area-preserving and non-Hamiltonian mapping

$$\mathcal{M} : (t_n, \mathbf{x}_n, \mathbf{v}_n) \mapsto (t_{n+1}, \mathbf{x}_{n+1}, \mathbf{v}_{n+1}) \quad (4)$$

Since it is not clear a priori whether the respective next collision happens with the boundary or with the inset, both are calculated and the smaller one is selected. In the following the iteration of the mapping is discussed for the possible cases, collisions with the oval boundary and the elliptical inset.

Collision with the oval boundary: First on, the slope of the trajectory after the respective last collision is calculated, then position and velocity and finally the corresponding time of the next collision follow. Let α_n measure the angle between the tangent to the boundary at the n -th collision point and the x -axis and β_n the angle between the velocity vector and the x -axis at this collision point (cf. 1). Then, the slope of the tangent at the n -th collision point $m_{B,n}$ can be calculated by

$$m_{B,n} = \left. \frac{dy_B(\phi)}{dx_B(\phi)} \right|_{\phi=\phi_n} = \left. \frac{dy_B/d\phi}{dx_B/d\phi} \right|_{\phi=\phi_n} = \frac{(1 - \delta/2) \sin \phi + (\delta/2) \sin(3\phi)}{(1 + \delta/2) \cos \phi + (\delta/2) \cos(3\phi)} \quad (5)$$

and $\alpha_n = \arctan(m_{B,n})$ holds. With $\beta_{n+1} = 2\alpha_n - \beta_n$ the trajectory after the n -th collision has the slope $m_{T,n} := \tan(\beta_{n+1})$, i.e. it evolves along a straight line with a known slope of $y(x) = m_{T,n}(x - x_n) + y_n$. Inserting the boundary-functions $x_B(\phi)$ and $y_B(\phi)$ (Eq. 1) for x and y yields an implicit equation determining the value of the angle at which the particle hits the boundary (in the inset-free) case at the respective next collision:

$$\begin{aligned} g(\phi) &:= m_{T,n} [(\delta/2 + 1) \sin \phi + (\delta/6) \sin(3\phi)] \\ &- [(\delta/2 - 1) \cos \phi - (\delta/6) \cos(3\phi)] + (y_n - m_{T,n}x_n) = 0 \end{aligned} \quad (6)$$

This implicit equation determines the boundary parameter $\phi_{n+1} \equiv \phi$ corresponding to the respective next collision point of particle and oval and can be solved numerically with a

standard Newtonian root finding method. Inserting ϕ_{n+1} into Eq. (1) yields the collision points in configuration space $x_{n+1}^B = x_B(\phi_{n+1})$ and $y_{n+1}^B = y_B(\phi_{n+1})$. Therein the superscript B denotes the collision with the static boundary. With Eq. 3 and $\mathbf{x}_{n+1} - \mathbf{x}_n$ being parallel to $\mathbf{v}_n$, the corresponding collision time results as $t_{n+1}^B = (-m/k) \ln [1 - k|\mathbf{x}_{n+1} - \mathbf{x}_n|/(mv_n)] + t_n$. The new velocity $\mathbf{v}_{n+1}^B$ directly follows with $v_{n+1}^B = v_n \cdot \exp [(-k/m)(t_{n+1} - t_n)]$ and $v_{n+1}^y/v_{n+1}^x = \tan(\beta^{n+1}) = m_{T,n}$.

Collision with the oscillating elliptical inset: In contrast to the oval boundary, for calculating the collision time with the inset, advantage can be taken from the fact, that a coordinate representation for the ellipse exists. Inserting Eq. (3) with $\mathbf{v}_0 \mapsto (v_{x,n}, v_{y,n})$ and $t \mapsto t_{n+1} - t_n$ component-wise into Eq. 2 yields the following implicit equation determining the time t_{n+1} of the respective following collision with the inset:

$$\begin{aligned} & \left[x_n + \frac{v_{x,n}m}{k}(1 - e^{-\frac{k}{m}(t_{n+1}-t_n)}) - f_x(t_{n+1}) \right]^2 / A^2 \\ & + \left[y_n + \frac{v_{y,n}m}{k}(1 - e^{-\frac{k}{m}(t_{n+1}-t_n)}) - f_y(t_{n+1}) \right]^2 / B^2 - 1 \\ & = : f(t_{n+1}) = 0; \quad t_{n+1} - t_n > 0 \end{aligned} \quad (7)$$

Note, that Eq. (7) only has a finite solution when $f(t_{n+1})$ changes sign at least once in the interval (t_n, t_{n+1}^B) . In this case, the respective smallest solution determines t_{n+1} and the respective next collision occurs with the inset. Otherwise $t_{n+1} = t_{n+1}^B$, $\mathbf{x}_{n+1} = \mathbf{x}_{n+1}^B$, $\mathbf{v}_{n+1} = \mathbf{v}_{n+1}^B$ is chosen. For a collision with the inset, the velocity changes as

$$\mathbf{v}_{n+1} = \mathbf{v}_n e^{[(-k/m)(t_{n+1}-t_n)]} - 2 [\mathbf{n} \cdot (\mathbf{v}_n e^{[(-k/m)(t_{n+1}-t_n)]} - \delta \mathbf{v}_I(t))] \cdot \mathbf{n} \quad (8)$$

where $\delta \mathbf{v}_I(t) = \partial_t \mathbf{x}_I(t)|_{t=t_{n+1}}$ is the velocity vector of the inset at the respective collision point and $\mathbf{n} = \delta \mathbf{v}_I(t)/|\delta \mathbf{v}_I(t)|$ is the corresponding normal vector. After each collision the slope can be directly updated via $m_{T,n+1} = v_{n+1}^y/v_{n+1}^x$ such that the respective part can be skipped above after a collision with the inset. All considerations concerning the time of the respective next collision of course hold independently of the sequence (boundary/inset) in which the collisions occur and the mapping can be straightforwardly iterated.

Particle Focusing The mapping is numerically iterated for ensembles of 10^4 initial conditions for $2.8 \cdot 10^6$ collisions and various choices of inset geometry and driving law. For the following discussion four representative examples are chosen. Initial velocities are chosen randomly with uniform probability in $v \in [5, 20]$ (the lower offset is to avoid particles stopping before hitting the inset for the first time). Regarding the evolution of the ensemble

FIG. 2. Time-evolution of the ensemble-averaged particle velocity. Parameters $\omega_x = \omega_y = 1.0$: Circle: $A = B = 0.5$; $a = b = 0.1$; $k = 0.002$; Ellipse 1: $A = 1.0$; $B = 0.25$; $a = 0$; $b = 0.25$; $k = 0.002$; Ellipse 2: $a = 1.3$; $b = 0.05$; $A = 0$; $B = 0.05$; $k = 0.001$; Ellipse 3: $a = 1.2$; $b = 0.05$; $A = 0.1$; $B = 0.05$; $k = 0.001$.

averaged magnitude of the velocity $\langle |v_n| \rangle$, according to Fig. 2, saturation is observed for all four visualized combinations of geometry and driving law. This saturation suggests that all particles have approached attractors, i.e. that the system is in its asymptotic state at the end of the simulation-time. For the circular inset (circle) and the relatively fast driven elliptical inset (ellipse 1) the average-velocity grows initially, then saturates at a certain value well above the average initial velocity. In contrast to that the average velocity decreases for both slowly driven elliptical billiards (ellipse 2,3) and converges towards values of $\langle |v_n| \rangle \sim 0.4$. Comparatively strong driving (for example $A = B = 0.3$ for the circular inset - not shown) leads to unbounded growth of energy on the examined timescales and is thus inappropriate in order to achieve particle focusing.

Now the asymptotic dynamics is analyzed in more detail. Fig. 3 (Circle) shows that the slowly driven circular inset leads to a broad asymptotic velocity distribution. Thus, it is inappropriate in order to achieve a focusing of particles on single trajectories. The broad dis-

FIG. 3. Velocity-distributions after $2.8 \cdot 10^6$ collisions. Parameters like in Fig. 2.

FIG. 4. Time-dependent magnitude of the velocity after $2.8 \cdot 10^6$ collisions for the configuration of ellipse 2 for two different initial conditions. Parameters like in Fig. 2.

tribution together with the observed saturation of the mean ensemble velocity is indicative of the presence of a strange attractor, i.e. that trajectories are asymptotically focused onto a submanifold with lower (and non integer) dimension than the phase space. An obvious conclusion would be to assume that circular insets do not allow for the presence of isolated attractive periodic orbits since defocussing is stronger than the focusing of the oval boundary in regions where attractors are conceivable. Thus, elliptical insets of elongated shape should be more promising. However, the velocity distribution (Fig. 3, ellipse 1) shows that

even the combination of a very flat elliptical inset and moderate driving is not sufficient in order to achieve particle focusing: again a stationary, i.e. non-spreading, but broad velocity distribution and corresponding chaotic motion of the respective trajectories is obtained.

A slowly and purely vertically driven flat elliptical inset provides an asymptotic velocity profile with two clearly pronounced peaks at $|v| \sim 0.2$ and $|v| \sim 0.4$ containing 92.7% of all initial conditions (Fig. 3, ellipse 2). Less than one percent of all particles are lost (low peak at $|v| = 0$). The peak at $|v| \sim 0.2$ corresponds to a periodic orbit attractor of period two. The corresponding asymptotic time-evolution of the magnitude of the velocity is shown in Fig. 4 (upper plot). The amplitude of the oscillations of $|v(t)|$ continuously decreases as the attractor is approached. The related motion in configuration space is a two-periodic bouncing exactly on the y -axis between inset and boundary. About 39.3% of all initial conditions are asymptotically focused on this periodic orbit and are thereby synchronized to perform asymptotically one and the same dynamics. The peak at $|v| \sim 0.4$ corresponds to a periodic orbit attractor of period four (Fig. 4, lower plot) which splits into four individual peaks in a very fine resolved version of Fig. 3 (ellipse 2) which merge in the long-time limit. About 53.4% of all initial conditions are focused on this periodic trajectory and are thereby perfectly synchronized in the long-time limit. In configuration space, the corresponding particles are focused on the same orbit as for the $|v| \sim 0.2$ peak. The remaining particles are focused on a variety of more complicated periodic trajectories, all in the velocity regime $0.2 < |v| < 0.39$ and very few ones on a trajectory around $|v| \sim 5$ (Inset in Fig.3, ellipse 2.). This demonstrates, that it is indeed possible to achieve the focusing of randomly distributed ensembles of neutral particles on periodic trajectories with close to perfect efficiency by using static oval billiards with elongated, slowly driven elliptical insets.

It is now suggestive that the respective, purely vertically aligned periodic orbit can also become attractive for a circular inset but with a much smaller basin of attraction. Since the circle is stronger defocussing than the boundary is focusing sophisticated time-correlations are required in order to approach it. Corresponding numerical simulations confirmed this expectation: for sufficiently slow driving, circular insets also yield attractive periodic trajectories and may thus be used in principle for particle focusing, but the corresponding efficiencies are extremely poor. The best achieved efficiency was well below 10%, i.e. typically most particles stop before reaching periodic orbits.

Further numerical simulations have been performed for a variety of combinations of slow

driving laws and elongated elliptical insets and always yielded both, the occurrence of fixed point attractors in phase space and small loss rates. Consequently the demonstrated particle focusing does not require any fine tuning of parameters. Fig. 3 (Ellipse 3) exemplarily shows the resulting velocity distribution for a slowly driven, vertically oscillating inset. Again, more than half of the ensemble is focused asymptotically onto the above-discussed period-four attractor, but the rest of the ensemble asymptotically follows a variety of periodic orbits with velocities between $|v| \sim 0.18$ and $|v| \sim 0.55$. A very different velocity profile could be achieved for example for $a = 1.0; b = 0.05; A = 0.3; B = 0.0125; k = 0.001; \omega_x = 2.5; \omega_y = 0.5$ but only for the price that a relevant part of the ensemble is asymptotically governed by a chaotic attractor and thus remains non-synchronized.

Note that the particle-focusing mechanism is governed solely by the topological structure of the phase space and thus works independently of the specific choice of the initial conditions. Key ingredients for high efficiency focusing are strong curvature of the oval boundary at certain positions and elongated insets such that particles are trapped in the upper or in the lower half of the billiard for many collisions.

Finally, possible experimental implementations are discussed. The presented numerical results should be accessible to particle-clusters in a micromechanical realization of the billiard-system with medium. Alternatively, a purely optical verification of the mechanism should be equally possible by using atoms in laser-based optical traps of oval shape, counter-propagating laser fields yielding friction due to the optical molasses and an oscillating blue detuned laser taking the role of the oscillating, reflecting inset. According to the following consideration the parameter sets used in this work should be effectively accessible in both setups: In Eqs.(3),(6),(7),(8) the length scale occurs only in the driving amplitudes a, b and in $a\omega_x, b\omega_y$, the time-unit appears in the driving frequencies ω_x, ω_y , in $a\omega_x, b\omega_y$ and in the friction coefficient, while the mass only appears reciprocal to the friction coefficient which scales with mass and time scale. A desired friction coefficient can be effectively realized by choosing particles with appropriate mass or also via the frequency of the driving, but the latter determines the size of the billiard, which otherwise can be chosen arbitrarily, as long as $a\omega_x, b\omega_y$ are preserved.

Conclusion It has been demonstrated, that dynamical focusing of ensembles of neutral particles in energy and configuration space, is possible in billiards with static boundaries and an oscillating scatterer in the interior. Employing appropriate oval boundaries and

sufficiently slowly driven elongated elliptical insets, close to perfect efficiency can be achieved. The suggested focusing device can be implemented either in a micromechanical or in a purely optical setup yielding a versatile alternative to common focusing devices like lenses or collimators.
